The naturally occurring nitrogen (N) isotopes, ¹⁵N and ¹⁴N, exhibit different reaction rates during many microbial N transformation processes, which results in N isotope fractionation. Such isotope effects are critical parameters for interpreting natural stable isotope abundances as proxies for biological process rates in the environment across scales. The kinetic isotope effect of ammonia oxidation (AO) to nitrite (NO2-), performed by ammonia-oxidizing archaea (AOA) and ammonia-oxidizing bacteria (AOB), is generally ascribed to the enzyme ammonia monooxygenase (AMO), which catalyzes the first step in this process. However, the kinetic isotope effect of AMO, or ε_{AMO}, has been typically determined based on isotope kinetics during product formation (cumulative product, NO_2^-) alone, which may have overestimated ε_{AMO} due to possible accumulation of chemical intermediates and alternative sinks of ammonia/ammonium (NH₃/NH₄⁺). Here, we analyzed ¹⁵N isotope fractionation during archaeal ammonia oxidation based on both isotopic changes in residual substrate (RS, NH₄+) and cumulative product (CP, NO₂⁻) pools in pure cultures of the soil strain *Nitrososphaera* viennensis EN76 and in highly enriched cultures of the marine strain Nitrosopumilus adriaticus NF5, under non-limiting substrate conditions. We obtained ε_{AMO} values of 31.9–33.1% for both strains based on RS ($\delta^{15}NH_4^+$) and showed that estimates based on CP ($\delta^{15}NO_2^-$) give larger isotope fractionation factors by 6–8%. Complementary analyses showed that, at the end of the growth period, microbial biomass was ¹⁵Nenriched (10.1%), whereas nitrous oxide (N₂O) was highly ¹⁵N depleted (-38.1%) relative to the initial substrate. Although we did not determine the isotope effect of NH₄⁺ assimilation (biomass formation) and N₂O production by AOA, our results nevertheless show that the discrepancy between ϵ_{AMO} estimates based on RS and CP might have derived from the incorporation of ¹⁵N-enriched residual NH₄+ after AMO reaction into microbial biomass and that N₂O production did not affect isotope fractionation estimates significantly.

Keywords: ammonia oxidation, nitrification, nitrous oxide, stable isotope fractionation, Thaumarchaeota

INTRODUCTION

Knowledge of natural ¹⁵N abundances and of nitrogen (N) isotope fractionation effects associated with key microbial N transformation processes has contributed greatly to our understanding of the marine N cycle (Casciotti and Buchwald, 2012; Buchwald and Casciotti, 2013) and of terrestrial gaseous N emissions (Houlton and Bai, 2009), namely atmospheric N₂O sources and sinks (Yoshida and Toyoda, 2000), and biological N fixation (Vitousek et al., 2013). The oxidation of NH₄⁺ to NO₂—the first and rate-limiting step in nitrification—is a central process in the marine and terrestrial N cycles, as well as the major driver of a large N isotope effect that leads to formation of ¹⁵N-depleted products such as NO, N₂O, NO₂⁻, and NO₃⁻, while residual NH₄⁺ becomes ¹⁵N-enriched during that process (Mariotti et al., 1981; Sigman and Casciotti, 2001). A detailed understanding of N isotope effects of the range of N transformation processes is thus critical for adequate biological interpretation of natural ¹⁵N isotope patterns in the environment (Casciotti, 2016).

Besides the recently discovered comammox bacteria (Daims et al., 2015; van Kessel et al., 2015), ammonia oxidation is catalyzed by both ammonia-oxidizing archaea (AOA) and ammonia-oxidizing bacteria (AOB), with different relative contributions across ecosystems and environmental conditions (Prosser and Nicol, 2012; Prosser et al., 2019). On a cellular level, ammonia oxidation is a multi-step process that comprises different enzymatic reactions and chemical equilibrium processes, which can all contribute to the N isotope fractionation effects inferred from extracellular N pools (Casciotti et al., 2003; Santoro and Casciotti, 2011). The isotopic fractionation effect (ε) of ammonia oxidizers has been typically inferred based on changes in $\delta^{15}N$ of the cumulative product (CP) NO_2^- (ε_{CP}), and attributed to the initial enzymatic step catalyzed by the ammonia monooxygenase (AMO) enzyme, defined as ε_{AMO} . However, ε_{CP} estimates reflect the combined fractionation effects of the isotope equilibrium between NH₄⁺ and NH₃ [NH₃, the proposed substrate for ammonia oxidation, is depleted in ¹⁵N relative to NH₄⁺ (Hermes et al., 1985)], the AMO-catalyzed reaction, and accumulation of several intermediates derived from subsequent enzymatic processes (Casciotti et al., 2003). For instance, ε_{CP} estimates may be affected by the accumulation of essential intermediates, such as hydroxylamine (NH2OH) and by the production of gaseous N by-products (nitric oxide, NO; and nitrous oxide, N2O), which may represent further ¹⁵N fractionation steps. Consequently, this could result in a difference of kinetic isotope effect estimates derived from residual substrate (RS) and CP (Casciotti et al., 2003). Not only could these "leakage" processes alter CP-based estimates of ε_{AMO} , but their different contributions to ammonia utilization and to ε_{CP} may also underlie the large differences observed in ε_{AMO} between ammonia-oxidizing organisms (Mariotti et al., 1981; Yoshida, 1988; Casciotti et al., 2003; Santoro and Casciotti, 2011).

Estimates of isotope effects based on the change in $\delta^{15} NH_4^+$ (ϵ_{RS}) can circumvent many of the expected biases associated with ϵ_{CP} , as they are not affected by the multiple subsequent

equilibria, enzymatic transformations, and intermediate N pools, as discussed but not quantified previously (Casciotti et al., 2003; Santoro and Casciotti, 2011). However, to our knowledge, only one study has determined the isotope fractionation factors based on concurrent measurements of changes in isotopic composition of RS and CP of ammonia oxidation, namely in cultures of the AOB Nitrosomonas europaea (Mariotti et al., 1981). This study found no difference between ε_{RS} and ε_{CP} , suggesting that ammonia oxidation can be effectively regarded as a "one-step process," where the AMO-catalyzed reaction constitutes the rate-limiting and sole isotope fractionation step. On the other hand, AOB and AOA seem to harbor fundamentally distinct ammonia oxidation pathways and exhibit different yields of gaseous N compounds per mole of NH₄⁺ consumed (Walker et al., 2010; Kozlowski et al., 2016). Importantly, the enzyme hydroxylamine dehydrogenase (HAO), which performs the second step in ammonia oxidation of AOB, has not been identified in AOA, and thus it remains unclear how NH2OH is converted to NO2- in AOA (Walker et al., 2010; Kerou et al., 2016). Moreover, a recent study has provided evidence that the bacterial HAO oxidizes NH2OH to NO rather than to NO2-, as generally assumed, with the latter resulting from non-enzymatic oxidation of NO by oxygen (Caranto and Lancaster, 2017). Previous studies have shown that NO is also an essential intermediate in ammonia oxidation by AOA, as their growth and activity is highly sensitive to exposure to an NO scavenger (Shen et al., 2013; Kozlowski et al., 2016).

Here, we tested whether the kinetic isotope effect of archaeal ammonia oxidation based on CP (δ¹⁵NO₂-) alone might be biased, by comparing the isotope fractionation factors inferred from both RS and CP pools. For this, we determined the kinetic isotope effects during growth of two phylogenetically and ecologically distinct AOA: the axenic strain Nitrososphaera viennensis EN76 (Stieglmeier et al., 2014a), isolated from soil, and the highly enriched marine strain Nitrosopumilus adriaticus NF5 (Bayer et al., 2016). This is also the first study of ¹⁵N isotope fractionation of ammonia oxidation by an AOA strain in pure culture. All previous studies of kinetic isotope effects of AOA have been performed with enrichment cultures with varying degrees of enrichment (Santoro and Casciotti, 2011; Nishizawa et al., 2016) and bacterial contaminants that may have contributed to the variation in isotope effects through consumption of and inputs to the same N pools.

MATERIALS AND METHODS

Pure cultures of N. viennensis EN76 were cultivated in freshwater medium and incubated at 37° C, as described by Tourna et al. (2011). In a first experiment, quadruplicate cultures were supplemented with 1 mM NH₄⁺ and 0.1 mM pyruvate; in a second experiment, quadruplicate cultures were supplemented with 2 mM NH₄⁺ and 0.5 mM pyruvate to generate higher cell biomass and sufficient N₂O concentrations for isotopic analysis, in order to determine their potential effect on ε_{AMO} . Quadruplicate enrichment

cultures of *N. adriaticus* NF5 were cultivated in Synthetic Crenarchaeota Medium (SCM) at 30°C as described by Bayer et al. (2016). The medium was supplemented with 1 mM NH₄+ and 5% (v/v) autoclaved seawater, which was sterile-filtered (0.22 μ m GTTP, Millipore). Kanamycin at a final concentration of 100 μ g ml⁻¹ was used to inhibit bacterial contaminants. At the time of the experiment (January 2013), the enrichment level of strain NF5 was ~95%, as it contained a heterotrophic non-nitrifying/non-denitrifying contaminant of the alphaproteobacterial species *Oceanicaulis alexandrii* (Bayer et al., 2019).

Ammonia-oxidizing archaea growth was monitored by measuring nitrite production using the Griess method (Hood-Nowotny et al., 2010), coupled to NH₄⁺ consumption determined using the Berthelot method for N. viennensis cultures (Hood-Nowotny et al., 2010) and the o-Phthalaldehyde (OPA) method for N. adriaticus cultures (Goyal et al., 1988). δ¹⁵NH₄⁺ was quantified by microdiffusion (Sørensen and Jensen, 1991) with subsequent analysis on a continuous-flow isotope ratio mass spectrometer consisting of an elemental analyzer (EA1110, CE Instruments) coupled via a ConFlo III interface (Finnigan MAT, Thermo Fisher Scientific) to the isotope ratio mass spectrometer (IRMS; DeltaPLUS, Finnigan MAT, Thermo Fisher Scientific). δ¹⁵NO₂ was determined based on the reduction of NO2- to N2O by azide under acidified conditions (Lachouani et al., 2010). Concentrations and isotopic ratios of N2O were determined using a purge-and-trap GC/IRMS system (PreCon - GasBench II headspace analyzer, Delta Advantage V IRMS; Thermo Fischer Scientific, Vienna, Austria). For NH₄⁺ and NO₂⁻ isotope measurements, we included blanks, concentration standards, and isotope standards varying in natural ¹⁵N abundance together with the samples through the full microdiffusion and azide procedures to allow corrections for blank contribution, incomplete reaction, and procedural isotope fractionation (Lachouani et al., 2010). Nitrogen content and 815N signature of AOA biomass were determined by EA-IRMS as described above. $\delta^{15}N$ signatures [\% vs. AIR] were calculated relative to the ratio R (15N:14N) of the atmospheric N₂ standard (AIR), as $\delta^{15}N = (R_{sample}/R_{standard})$ $-1) \times 1000.$

Isotope fractionation factors (ϵ) were calculated based on the Rayleigh closed system isotope fractionation, based on changes in the isotopic compositions of RS (i.e., NH₄⁺) and CP (i.e., NO₂⁻) (Mariotti et al., 1981):

$$10^{3} \ln \frac{10^{-3} \delta_{RS} + 1}{10^{-3} \delta_{S0} + 1} = \varepsilon \ln(f)$$
 (1)

$$\delta_{CP} - \delta_{S0} = -\varepsilon f \frac{\ln(f)}{(1-f)},\tag{2}$$

where δ_{S0} is $\delta^{15}N$ of initial NH_4^+ , δ_{RS} is $\delta^{15}NH_4^+$, δ_{CP} is $\delta^{15}NO_2^-$ and f is the fraction of the initial $[NH_4^+]$ remaining in the culture. Plots of $10^3 \frac{10^{-3}\delta_{RS}+1}{10^{-3}\delta_{S0}+1}$ versus $\ln(f)$ and of $\delta_{CP} - \delta_{S0}$ versus $f\frac{\ln(f)}{(1-f)}$ yield linear relations, with the slope representing the kinetic isotope effect based on the isotopic change in

substrate (ε_{RS}) and product (ε_{AP}), respectively. Uncertainties of ε are expressed as standard error of the slope. Differences in isotope fractionation effects between cultures were assessed by testing significant differences between their regression plots, using R (R Development Core Team, 2012).

RESULTS AND DISCUSSION

Based on the oxidation of NH₃/NH₄⁺ to NO₂⁻—a typical proxy for ammonia oxidizer growth, as it strongly correlates with growth rates (Stieglmeier et al., 2014a; Bayer et al., 2016)—all cultures showed growth curves typical for batch cultures of AOA, reaching stationary phase after 7 days for N. adriaticus, and after 3-4 days for N. viennensis cultures (Figures 1A-C). Nitrogen isotope fractionation was reflected in both the substrate (i.e., NH₄⁺) and the product (i.e., NO₂⁻) of ammonia oxidation, and followed typical Rayleigh isotope fractionation kinetics for closed systems (Figures 1D-F): NH₄⁺ became increasingly ¹⁵N-enriched with the fraction of NH₄⁺ oxidized, while NO₂⁻ was strongly 15N-depleted after correction for NO2- deriving from the inoculum. With an increasing fraction of NH₄⁺ oxidized, δ¹⁵NO₂ converged toward the isotopic signature of the initial NH₄⁺. Both N. adriaticus and N. viennensis (including cultures grown on 1 and 2 mM NH₄⁺) exhibited ¹⁵N isotope fractionation factors based on substrate (ε_{RS}) between 31.9 and 33.1\%, and based on product (ε_{CP}) between 37.7 and 49.1% (Figures 2A-F). We found no significant difference between the isotope fractionation factors of the different AOA cultures studied here based on δ¹⁵N evolution of the substrate (ε_{RS} ; comparison of slopes, df = 2, F = 0.519, p = 0.598) or the product (ε_{CP} ; comparison of slopes, df = 2, F = 2.380, p = 0.102). The N isotope fractionation factors based on $\delta^{15}NO_2^-$ (ϵ_{CP}) were larger than those based on $\delta^{15}NH_4^+$ (ϵ_{RS}) by 8.0, 5.8, and 5.9% for N. adriaticus, and for N. viennensis grown on 1 mM or 2 mM NH_4^+ , respectively.

Nitrogen isotope fractionation has been studied in several AOB strains, but only in three marine and one thermophilic AOA enrichment cultures. These AOA enrichment cultures showed average N isotope fractionation factors between 22 and 25\%0 at low substrate concentrations, and up to 32.0% at higher ammonium concentrations (Santoro and Casciotti, 2011; Nishizawa et al., 2016, measured via the isotopic composition of the product nitrite; see Table 1). These estimates are in the same range as the reported average isotope effects for different AOB strains, i.e., 14-38‰ (Delwiche and Steyn, 1970; Mariotti et al., 1981; Casciotti et al., 2003). ¹⁵N isotope fractionation factors of N. viennensis and N. adriaticus are in the upper range, or higher, than those previously reported for AOA, which might be due to the higher ammonia concentrations applied in our study (1-2 mM in our study vs. 200 µM in Nishizawa et al., 2016; 10-75 µM in Santoro and Casciotti, 2011). Previous studies have indicated that higher initial ammonia concentrations lead to more stable

Some error bars are smaller than the symbol.

and higher ¹⁵N isotope fractionation (Casciotti et al., 2003; Santoro and Casciotti, 2011).

We also measured ϵ_{AMO} based on changes in $\delta^{15} N H_4^+$ (i.e., the residual substrate) to both circumvent and assess potential biases associated with estimates based on δ¹⁵NO₂⁻ (i.e., the cumulative product). It should be noted, however, that different apparent isotope effects in whole cells may also be observed in the NH₄⁺ pool, despite constant AMO enzymelevel isotope effects, depending, for example, on the balance between ammonia oxidation rates and ammonia diffusion across the S-layer (i.e., outermost cell envelope component in AOA) (Casciotti et al., 2003; Li et al., 2018). Published models of AOA and AOB metabolism favor the hypothesis of a (pseudo-)periplasmic location of the ammonia oxidation process (Arp and Stein, 2003; Walker et al., 2010; Simon and Klotz, 2013). However, AOA and AOB harbor very distinct NH₃/NH₄⁺ transport systems (Offre et al., 2014), whose role in ammonia oxidation and contribution to observed differences in ¹⁵N isotope fractionation remain unclear (Arp and Stein, 2003). At low ammonia concentrations, ammonia oxidation rates are expected to become limited by NH₄⁺ transport/NH3 diffusion, resulting in the convergence of the isotope effect toward that of NH₄⁺/NH₃ equilibrium (if NH₃ is mainly taken up by the cells) or NH₄+/NH₃ transport. The NH₄⁺/NH₃ equilibrium isotope effect has been estimated to

be 19.2\% in aqueous solution (Hermes et al., 1985), whereas secondary active ammonium (AMT) transporters, which are highly expressed in AOA (Carini et al., 2017), have been shown to exert isotope fractionation of around 13-15\%, due to deprotonation of NH₄⁺ during transport (Ariz et al., 2018). It is unlikely that ammonia oxidation has been limited by NH₃ availability in our study, because of the high substrate concentrations used, which are well above the K_m of the AMO of N. viennensis (5.4 μ M NH₃ + NH₄⁺; Kits et al., 2017) and that of the marine strain Nitrosopumilus maritimus strain SCM1 (0.13 μ M NH₃ + NH₄⁺; Martens-Habbena et al., 2009), which is closely related to N. adriaticus. Furthermore, Nishizawa et al. (2016) estimated that, when NH₃ concentrations in the pseudo-periplasm are lower than in the medium under laboratory conditions, cell-specific NH3 diffusion rates into the pseudo-periplasm are higher than cell-specific ammonia oxidation rates. It has also been proposed that the charged S-layer proteins of AOA enhance the diffusion of charged solutes, such as NH₄⁺, which concentrates NH₄⁺ in the pseudo-periplasmic space near the active site of the AMO (Li et al., 2018), where then the equilibrium reaction between NH₄⁺ and NH₃ is relatively fast and considered not to be rate-limiting.

Even if ammonia oxidation was not limited by periplasmatic NH₃ availability, the apparent isotope effect of the AMO can

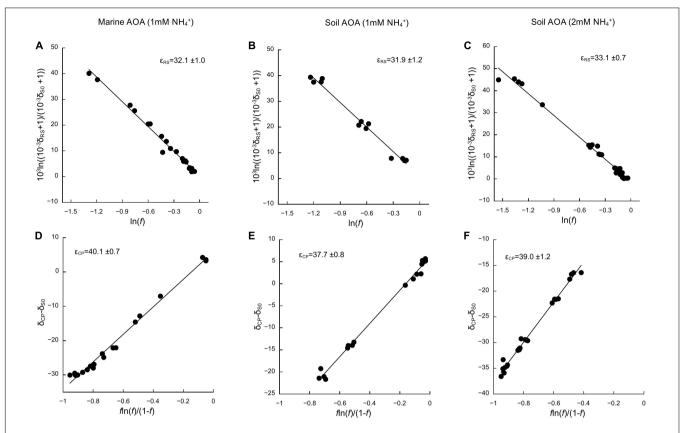

FIGURE 2 | Kinetic isotope effects of the marine AOA N. *adriaticus* and the soil AOA N. *viennensis*. Isotope fractionation factors (ϵ_{RS} and ϵ_{CP}) were calculated based on changes in **(A–C)** δ^{15} N-NH₄⁺ (δ_{RS}) and **(D–F)** δ^{15} N-NO₂⁻ (δ_{CP}), using linear regressions of $10^3 \frac{10^{-3} \delta_{RS} + 1}{10^{-3} \delta_{SO} + 1}$ versus ln(f) and $\delta_{CP} - \delta_{SO}$ versus f(f) and f in the culture. Uncertainties of f are expressed as SE of the slope. We used multiple-point estimates because they have lower uncertainty than single-point analyses.

also be underestimated due to concurrent NH₄⁺ assimilation, which has a smaller isotope effect. This process would alter observed ε_{RS} estimates in proportion to the amount of NH₄⁺ assimilated and the isotope effect for NH₄⁺ assimilation (4-27%; Hoch et al., 1992). Therefore, we also measured $\delta^{15}N$ of the cell biomass at the end of incubation of N. viennensis grown on 2 mM NH₄⁺ (Figures 1F, 3). Although it is impossible to infer directly the contribution of N assimilation to ε_{RS} from just one end-point measurement, we propose that N assimilation substantially contributed to the decrease of ε_{RS} relative to ε_{CP} in our study, as biomass was ^{15}N enriched by $\sim 10\%$ compared to initial NH₄⁺. Biomass N represented 3.1% (± 0.3 SE) of ammonia oxidized by N. viennensis grown on 2 mM NH₄⁺. Although dissolved inorganic N (DIN) concentrations (sum of [NH₄⁺] and [NO₂⁻]) were relatively constant over the course of ammonia oxidation, we recovered only 81.9% (± 1.5 SE) of the initial DIN by the end of incubation of N. adriaticus, and 94.7% (± 3.4 SE) and 90.7% (± 1.1 SE) of N. viennensis grown on 1 mM NH₄⁺ or 2 mM NH₄⁺, respectively. In N. adriaticus cultures, assimilation of N by contaminant bacteria likely did not contribute substantially to the lower ε_{RS} relative to ε_{CP} , due to the high enrichment level of the culture (95%) at the time

of the experiment, and the fact that ε_{RS} of N. adriaticus was similar to that of N. viennensis in pure culture. In addition, the ¹⁵N-enrichment of N. viennensis' biomass shows that AMO preferentially, and primarily, reacts on pseudo-periplasmatic NH₃, causing ¹⁵N-enrichment of the residual ammonia, which is subsequently assimilated into biomass. We thus propose that under substrate replete conditions, the observed isotope effects of ε_{RS} of 31.9–33.1% primarily reflect the kinetic isotope effect of the AMO-catalyzed reaction, modified by the NH₄⁺/NH₃ equilibrium isotope effect (19.2%; Hermes et al., 1985) and decreased by the contribution of the lower kinetic isotope effect of NH₄⁺ assimilation for anabolic purposes (4–27‰; Hoch et al., 1992). Moreover, it should be noted that some ammonia oxidizers use distinct pathways of NH₄⁺ assimilation, even among just AOA, which may contribute to different kinetic isotope effects. For instance, some members of the AOA genus Candidatus Nitrosocosmicus appear to assimilate NH₄⁺ via glutamate synthase (GOGAT), whereas all other known AOA use the glutamate dehydrogenase (GDH) pathway (Alves et al., 2019).

Despite these potential isotope fractionation effects on the RS level, a higher ϵ_{CP} relative to ϵ_{RS} may also result from accumulation of metabolic intermediates, allowing for at least

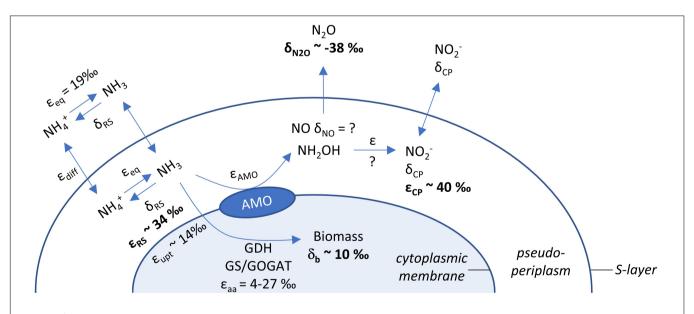

FIGURE 3 | Schematic overview of processes and isotope fractionation effects involved in ammonia oxidation, growth and intermediate formation of the soil AOA N. viennensis. $\delta^{15}N$ values are given for endpoint measurements of N_2O and biomass, while average kinetic isotope effects of ammonia oxidation are presented for substrate (N_4^+ , ϵ_{RS}^-) and product (N_2^- , ϵ_{CP}^-). Literature values for isotope fractionation of N_3^+/N_4^+ equilibration (ϵ_{eq}^- ; causing N_2^-) and depending one of N_3^- and its inherent isotope fractionation are currently unknown for AOA.

TABLE 2 Nitrogen pools for *N. viennensis* culture grown on 2 mM NH₄⁺.

	N pool (μM)	δ ¹⁵ N of N pool (‰)	Percent of missing N pool	Percent of ammonia oxidized
Missing	204.4 (±25.2)	-7.6 (±5.2)		
Biomass	38.8 (±3.4)	10.1 (±0.1)	22.8 (±4.1)	$3.1 (\pm 0.3)$
N ₂ O-N	$6.5 (\pm 0.2)$	$-38.1 (\pm 0.3)$	3.5 (±0.4)	$0.5 (\pm 0.1)$
Unaccounted	139.2 (±27.1)	$-18.5 (\pm 1.7)$	73.7 (±4.5)	

The missing N pool is N that was not present at NH_4^+ and NO_2^- at the last sampling time point when biomass and N_2O was collected for isotope analysis. We used a mass balance approach to calculate $\S^{15}N$ of the missing and unaccounted N pool. Standard errors are given in parentheses.

a second ¹⁵N isotope fractionation step to be observed. First, accumulation of NH2OH, or any other intermediate, has not been observed in AOA cells, and the coupled activities of AMO and hydroxylamine oxidoreductase (yet unknown in AOA) are assumed to maintain NH₂OH at low steady-state concentrations. Therefore, isotope effects associated with NH2OH oxidation should have a limited impact on δ¹⁵NO₂⁻. Second, any process that adds an additional isotope fractionation step, either prior, or subsequent, to NO₂⁻ formation, such as the production of the gases NO and N2O, may result in an under- or overestimation of the kinetic isotope fractionation factor. The effect of N2O and NO production on $\delta^{15}NO_2^-$ will depend on their formation pathways, and respective isotope effects and by-product yields. In the N. viennensis culture grown on 2 mM NH₄+, we measured cumulative N2O at the end of the incubation, which represented 0.5% (± 0.01 SE) of the NH₄⁺ oxidized, or 3.5% (±0.4 SE) of the "missing" N pool. N2O yields of AOA are generally low. For example, N. viennensis has been shown to produce N2O at rates of about 0.1% of those of ammonia oxidation when grown on 1 mM NH₄+/NH₃ (Stieglmeier et al., 2014b), whereas the marine AOA N. maritimus SCM1 produces even less (0.002-0.03%; Löscher et al., 2012). Here, the cumulative N_2O of the N. viennensis culture had a $\delta^{15}N$ of -38.1% (± 0.3 SE) (Figures 1F, 3), which was more 15 Ndepleted than previously observed for AOA enrichment cultures. AOA have been shown to produce N₂O with δ¹⁵N signatures ranging between -35 and -13% in soil enrichment cultures and -9% in marine enrichment cultures (Santoro et al., 2011; Jung et al., 2014), while N2O produced by AOB tends to have lower δ^{15} N, ranging between -66% (Nitrosomonas europaea; Yoshida, 1988) and -10% (Nitrosomonas marina; Frame and Casciotti, 2010). Furthermore, by-products that are more ¹⁵Ndepleted than the main product of ammonia oxidation (i.e., NO₂⁻) would decrease the apparent kinetic isotope effect of AMO (ε_{CP}), instead of increasing it. Using an isotopic mass balance approach, we calculated that the missing N pool (i.e., the NH₄⁺ taken up which was not oxidized to NO₂⁻), would need to have a δ^{15} N of -18.5%0 (± 1.7 SE) in order to account for the difference in isotope fractionation between ε_{RS} and ε_{CP} (**Table 2**). Therefore, the $\delta^{15}N_2O$ signature of -38.1%0 cannot explain the observed large isotope fractionation based on δ¹⁵NO₂⁻, since

the N_2O produced would need to be a larger contributor to the "missing" N pool, as well as to be ^{15}N -enriched relative to NO_2^- .

Nitric oxide is an important intermediate in the ammonia oxidation pathway, particularly in that of AOA. Unlike in AOB, NO is a necessary co-reactant for the oxidation of NH₂OH to NO₂⁻ in AOA, despite being produced in relatively small amounts (Kozlowski et al., 2016). Although the δ^{15} N signature of NO produced by AOA has not yet been determined, Yoshida (1988) found that NO produced during nitrification by *N. europaea* had a δ^{15} N between 0 and +20‰. The production of such ¹⁵N-enriched NO could significantly contribute to the observed overestimation of ϵ_{CP} in AOA.

CONCLUSION

In conclusion, our results show that, under non-limiting substrate conditions, the ϵ_{AMO} of two phylogenetically and ecologically distinct AOA strains was 31.9-33.1% based on $\delta^{15} N H_4^+$, whereas the more commonly estimated ϵ_{AMO} based on $\delta^{15} N O_2^-$ was higher (37.7–40.1%). Thus, $N H_4^+$ assimilation, but not $N_2 O$ production, significantly affected the isotope fractionation factor of AMO estimated for *N. viennensis* (**Figure 3**). Although the potential role of NO in this context remains to be tested, isotopic analysis of this molecule is difficult and therefore future measurements of ϵ_{AMO} may rely on coupled estimates from $\delta^{15} N H_4^+$ and $\delta^{15} N O_2^-$.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusion of this article have been deposited at DRYAD (doi: 10.5061/dryad.0gb5mkkz1).

AUTHOR CONTRIBUTIONS

WW designed the study. MMo, RA, BB, MMe, MS, LJ, SR, and MW performed the experiments. MMo, RA, BB, MS, and LJ analyzed the data. GH and CS provided the resources and strains. MMo, RA, and WW wrote the manuscript with contributions from all co-authors.

FUNDING

This study was funded by the Austrian Science Fund (FWF; project P28037-B22). Open access funding was provided by University of Vienna.

ACKNOWLEDGMENTS

We thank the students of the course "Stable Isotopes in Ecology" of the years 2012–2014 at the University of Vienna, who contributed to the sample analyses and discussion of the data.
